UTERINE RUPTURE ASSOCIATED WITH PLACENTA ACCRETA IN A COMMUNICATING PSEUDO-UNICORNUS: A CASE REPORT AND REVIEW OF THE LITERATURE

Abstract

Introduction

Uterine malformations are abnormalities of the development of the Müllerian ducts and represent 1 to 4% in terms of prevalence in the population.

Pregnancy constitutes a circumstance of discovery of this congenital anomaly with an increased risk of obstetrical complications, the most dreaded of which are ectopic pregnancy and uterine rupture.

Observation

We report in our observation a case of uterine malformation associated with pregnancy. This was a 20 years old female patient with a 34 SA pregnancy who presented with abdomino-pelvic pain. On clinical examination a threat of preterm delivery was suspected. Obstetrical ultrasound revealed a praevia mass suggesting adnexal torsion or a praevia myoma. A laparotomy was carried out, which revealed a communicating pseudo-unicornuate uterus (AFS class II type 3) with the pregnancy located in the communicating part. A subserous uterine rupture associated with a placenta accreta was noted at this level. Fetal extraction was performed followed by a hemostasis hysterectomy. The postoperative course was unremarkable with a healthy live infant.

Conclusion

These rare cases require a good prenatal follow-up with early ultrasound. This is often difficult in rural areas where the low socio-economic level favors a delay in diagnosis and management and the mode of discovery remains during an obstetrical complication.

INTRODUCTION

Uterine malformations are abnormalities of the development of the Müllerian ducts and represent 1 to 4% in terms of prevalence in the population.

Pregnancy constitutes a circumstance of discovery of this congenital anomaly with an increased risk of obstetrical complications, the most dreaded of which are ectopic pregnancy and uterine rupture.

We report in our observation a case of uterine malformation associated with pregnancy.

OBSERVATION

Mrs. M.D.G., 20 years old, came on her own for abdomino-pelvic pain associated with a pregnancy of 33 SA. In her obstetrical history, she is a second gesture second pare all delivered by vaginal route without notion of complications.

She had three prenatal consultations without any particularities, with a prenatal check-up done without any particularities. She benefited from an obstetrical ultrasound performed late in the pregnancy at 19 weeks of age without any other anomaly being detected.

On admission, the general examination was normal. Obstetrically, the diagnosis of a moderate threat of labor according to the Baumgarten score was retained and the patient was hospitalized. Tocolysis with salbutamol and pulmonary maturation were initiated.

Ultrasound performed in the department revealed a heterogeneous praevia mass measuring 96 mm in long axis, as well as a total overlying placenta praevia (**Figures 1 and 2**). The hypothesis of adnexal torsion or necrobiosed myoma praevia was put forward.

A remission of the symptomatology was observed during her hospitalization but 5 days later the abdominal pain resumed, which led to the indication of an emergency exploratory laparotomy.

At the exploration we noted the existence of a communicating pseudo unicornuate uterus (**figures 3,4 and 5**); with the pregnancy localized at the level of the communicating part (**figure 6**), with a beginning of uterine rupture under serosa associated with a placenta praevia accreta.

A caesarean section followed by a hemi-hysterectomy was performed which allowed the extraction of a live female infant weighing 1700g.

The postoperative course was simple and the hospital stay was 5 days.

The malformative workup done at a distance came back normal.

DISCUSSION

The discovery of a uterine malformation during pregnancy is rare.

Indeed, in the literature, the prevalence of these cases is estimated at 1/100000 or even 1/140000.

The positive diagnosis of a pregnancy on a rudimentary horn of a pseudo unicornuate uterus suffers from a delay in our context related to several factors: the diagnostic delay due to diagnostic wandering, the poor technical platform especially in rural areas and the presence of ultrasound equipment of low quality.

Furthermore, even with the availability of a good quality ultrasound machine, there remains a difficulty in ultrasound diagnosis. Tsafir et al proposed criteria for early ultrasound diagnosis of pregnancies on a rudimentary horn of a pseudo unicornuate uterus, namely: a pseudo picture of an asymmetric bicornuate uterus, absence of visual continuity between the cervix and the lumen of the horn containing the pregnancy; presence of myometrial

tissue around the gestational sac and more or less the presence of hypervascularization typical of a placenta accreta [13].

The differential diagnosis during exploratory laparotomy for uterine rupture between pseudo unicornuate uterus with rudimentary horn (type IIa or IIb of the AFS classification) and bicornuate uterus (IVb and especially IVa of the AFS classification) remains difficult as shown by our observation. This difficulty is reinforced by the fact that in some cases reported in the literature, there are approximations that do not allow precise differentiation of the two malformations [2,3,10]. Their distinction is all the more difficult as the rudimentary uterine horn is gravid and therefore of at least the same size as the main uterine horn.

Pregnancy in a rudimentary horn is associated with an increased risk of delayed uterine rupture in 50 to 80% of cases [8]. This fragility is explained by the distension of the horn, which leads to its rupture when the stretch following gestation becomes too great.

This fragility may be accentuated by pathological placental implantation (placenta accreta and percreta), leading to erosion of the horn [9]. These placental anomalies are favored by a poor quality endometrium and a thin myometrial thickness. Uterine rupture occurs mainly in the second trimester in 60 to 90% of cases [6]. In case of discovery of a pregnancy on a rudimentary horn, the continuation of the pregnancy or the achievement of a medical termination of pregnancy can be debated. Indeed, it is frequent and there is currently no way to prevent this complication.

Most of the cases described concern monofetal pregnancies. A case of twin pregnancy in a pseudo unicornuate uterus evolving in each of the horns was described by Ejnès et al, with a preventive extraction of the two fetuses at 22 weeks of amenorrhea [5]. Three other cases have been described since 1945 in the literature [5,11].

The surgical management of this malformation during pregnancy is based on excision of the rudimentary horn associated with ipsilateral salpingectomy. This procedure can be performed by laparotomy or laparoscopy [1,12].

Neoadjuvant medical treatment with methotrexate has also been described but the benefit of this treatment remains to be evaluated [4].

It seems necessary to refer these patients to a multidisciplinary prenatal diagnosis center (CPDPN) [7]; this is difficult in sub-Saharan Africa where such multidisciplinary centers are not yet in place.

CONCLUSION

These rare cases require good prenatal follow-up with early ultrasound. This is often difficult in rural areas where the socio-economic level favors a delay in diagnosis and management and the mode of discovery remains during an obstetric complication. Hence the interest of a rapid establishment of a multidisciplinary center for prenatal diagnosis.
