

Review Article

Titanium dioxide one dimensional nanostructures as photoanodes for dye-sensitized solar cells

Abstract

Herein, we reviewed the titanium dioxide one dimensional nanostructures which are commonly applied as photoanodes for dye sensitized solar cells (DSSCs). Titanium dioxide is the commonly used semiconductor electrode due to its low toxicity, mechanical stability, and availability during DSSCs application. The efficiency of the DSSCs having a titanium dioxide photoanode is mainly determined by the changes in the short circuit current (J_{sc}). The TiO_2 nanoparticles have shown an efficiency of 12 % which is the highest. Other nanostructures such as nanotubes (11.05 %), nanowires (8.90 %), and nanofibers (8.0 %) have also been used as anodes. The TiO_2 nanotubes have a high surface area that enhances dye loading but also increases the short circuit current hence leading to a high conversion efficiency (11.05 %). This review also introduces the commonly used characterization techniques for titanium dioxide nanostructures which explain crystal orientation, morphology, surface functional groups, surface area, elemental composition, and other chemical properties.

Keywords: titanium dioxide, short circuit current, photoanode, nanotubes, nanowires, efficiency

1. Introduction

In recent years the use of fossil fuels as a source of energy has seen a rapid increase due to several human activities such as mining, industrialization, and farming. These fuels which include coal and petroleum give off greenhouse gases that pollute air, land, and water thus endangering humans and aquatic life [1]. Utilization of solar energy as an alternative renewable energy source is an efficient and modest way as the irradiation that reaches the earth is significantly higher than the human energy demand [2]. It has been determined that the amount of solar radiation that reaches the Earth is 3.8 million EJ/year [3]. Research is currently ongoing to develop efficient solar energy capture, conversion, and cheap storage technologies, simple in design and non-toxic [4, 5]. In 1972 Honda and Fujishima used the photoelectric effect to explain

function is to collect and transport the electrons to the external circuit is of great importance in the DSSCs [15]. Semiconductor materials are mainly up of TiO_2 [16], SnO_2 [17], Fe_2O_3 [18], and ZnO [19, 20] which have found wide application as anode electrodes in DSSCs. The nanostructured TiO_2 materials have found application as semiconductor materials due to their large surface area which improves dye loading and the overall efficiency of the cell. The commonly used semiconductor nanostructures include nanowires, nanoparticles, nanotubes, nanoflowers, nanoribbons, nano-onions, nanoflakes, and nanofibers. Titanium dioxide nanoparticles having ruthenium as the dye sensitized have conversion efficiencies of 12 % in the lab and 32 % theoretically [21, 22]. The light scattering drawbacks and low conversion efficiencies faced by TiO_2 nanostructures can be solved through doping which improves the efficiency. A number of cations such as Tungsten (W)[23], Nickel (Ni) [24], Niobium (Nb) [25], and Lanthanum (La) [26] have been used as dopants to improve electron mobility and light absorption. Also, non-metals such as Fluorine (F)[27], Carbon (C)[28], Nitrogen (N)[29, 30], and Sulphur (S)[31] have also been applied to modify the electronic properties of TiO_2 . This review aims to illustrate the Titanium dioxide photoanode nanostructures and how they influence the dye sensitized solar cell performance. Furthermore, different photoanode characterization techniques are discussed as well as the overall performance of the nanowires, nanoparticles, nanotubes, and nanofibers.

2. Working principle and photochemical characterization techniques of DSSCs

The dye sensitized solar cell consists of five components which include the semiconductor, electrolyte with its redox couple, dye sensitizer, counter electrode, and transparent conductive oxide as shown in Figure 2.

Figure 2. Electron transfer in the various dye sensitized solar cell components.

The dye sensitizer plays the role of absorbing a photon of energy which generates an electron through excitation from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) which leads to injection of the charges to the conduction band of the metal oxide. The semiconductor which is usually made of TiO_2 serves the function of acting as an anchor onto which the load gets attached through its large surface area but also a wide band gap for light harvesting. In addition, the transparent conductive which is either made of Fluorine or Indium acts as a support for the semiconductor but also to transport the electrons to the external load. Furthermore, the electrolyte mainly containing iodide/triiodide redox couple acts as an electrical medium between the counter electrode and the working electrode but also in the regeneration of the oxidized dye sensitizer molecule. Lastly, the counter electrode plays an important role in returning the electron to the circuit but also acts as an electrocatalyst for better photovoltaic performance.

The characterization of the photovoltaic performance of the dye sensitized solar cells is mainly carried out using the three main techniques that are Photocurrent – voltage (I-V) measurements, Electrochemical Impedance Spectroscopy (EIS), and Incident to photon current conversion efficiency (IPCE).

Photocurrent–voltage (I-V) measurements are used to determine the electrical output power at 1.5 standard global air Mass (AM) and solar radiation of 1000 W/m^2 occurring at a temperature of $25 \text{ }^\circ\text{C}$ [32]. It gives four parameters which include the open circuit voltage (V_{oc}), short circuit current (J_{sc}), fill factor (FF), and power conversion efficiency (PCE, η) as shown in Figure 3[33].

Figure 3. I-V curve showing the different photochemical parameters. Reprinted with permission ref [33]. Copyright 2011, The Royal Society of Chemistry

The open circuit voltage (V_{oc}) is defined as the maximum voltage to the external load which is a result of the electron quasi-fermi level and the electron separation hole[34]. It gives information on the difference between the electrochemical potential of the redox couple and the fermi level of the photoanode. V_{oc} is measured at open circuit conditions for which the current that flows is zero ($I = 0$). The short circuit current (J_{sc}) is measured as the maximum current output of the solar cell. J_{sc} is measured at short circuit conditions for which the potential applied is zero ($V=0$) and is influenced by several factors such as the electrochemical properties of the photoanode when in contact with the electrolyte solution, molecular structure of the dye sensitizer, and amount of dye adsorbed on the photo anode[35]. J_{sc} is a result of the proportionality of the diffusion length and is defined as shown in (Equation 1).

$$J_{sc} = qG(L_n + L_p)(1)$$

In addition, the fill factor gives information regarding the ideality of the solar cell which in brief is the ratio of the maximum power (P_{\max}) to the product of V_{oc} and J_{sc} (Equation 2) and varies in the range of 0-1 which values influence the rectangular shape of the graph.

$$FF = \frac{P_{\max}}{V_{oc} \times J_{sc}} = \frac{V_{\max} J_{\max}}{V_{oc} \times J_{sc}} \quad (2)$$

Lastly, the power conversion efficiency of a solar cell is the ratio of the maximum power (P_{\max}) to the incident power (P_{in}) under illumination of 1.5 standard global Air Mass (AM). The increased overall power conversion efficiency of the cell is greatly influenced by high values of V_{oc} , J_{sc} , and FF as shown in (Equation 3).

$$\eta = \frac{P_{\max}}{P_{in}} = \frac{V_{oc} \times J_{sc} \times FF}{P_{in}} \quad (3)$$

In addition, Electrochemical Impedance Spectroscopy which is a dynamic technique gives information regarding the kinetics of charge and photochemical reactions in the DSSCs[36, 37]. The EIS, once a potential is applied, generates a small sine wave that influences the sinusoidal current output and sinusoidal alternating potential which are plotted against variation in frequency modulation but represented in phase shift and amplitude[38]. The ratio of current to voltage in the frequency domain is measured in both real and imaginary parts which defines the impedance (Z). It is observed that the impedance of a resistor is independent of frequency and has both real (Z') and imaginary (Z'') parts while the capacitor and inductor form variation with frequency and only have imaginary parts. The impedance is determined at various frequencies (ω) by schematic representations of Nyquist plots (Z' Vs Z'') and Bode plot $|Z|$ vs (ω), θ is the phase of Z (ω)[39]. The Nyquist plot of impedance spectrum as used in DSSCs contains three semicircles which are fitted by a transmission line equivalent circuit (TLC) as shown in Figure 4 [40].

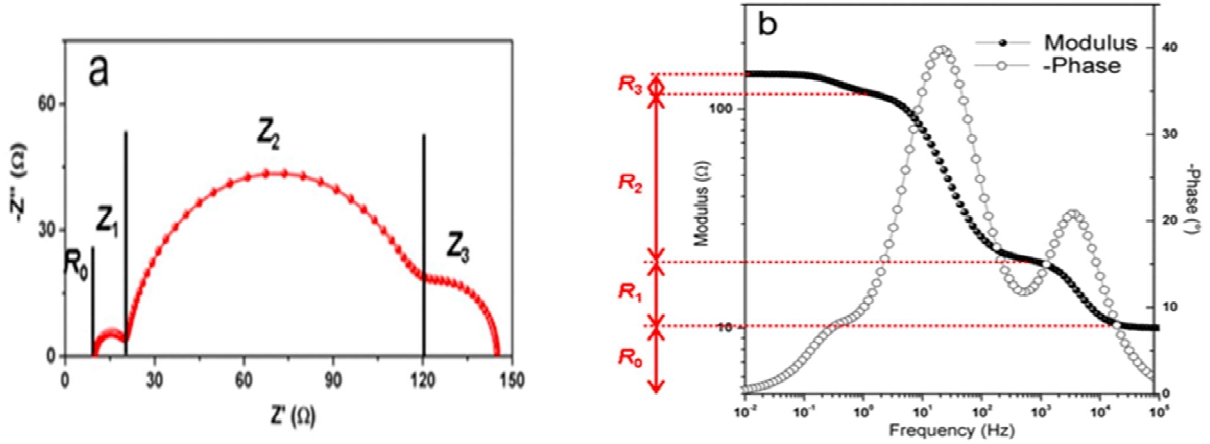

Figure 4. A schematic representation of Nyquist (a) and Bode (b) Plots. Reprinted with permission ref[40]. Copyright 2017, Elsevier

The semicircle is due to high frequency as a result of Helmholtz capacitance of the counter electrode and charge transfer resistance while the middle-frequency semicircle shows the capacitance of the photoanode and recombination resistance at the photoanode/electrolyte interface and the low-frequency semicircles describe the impedance diffusion in the electrolyte (Warburg element, W_s)[41, 42]. During DSSCs measured using EIS an electrical observation is made that the cell module consists of capacitors and resistors. EIS measurements are used to identify the capacitance and resistance in the different DSSCs components that is redox couple diffusion in the electrolyte, capacitance of the mesoporous metal oxide, charge transfer resistance of the counter electrode, recombination resistance at the interfaces of the semiconductor/dye/electrolyte and series resistance due to sheet resistance of TCO at the contact resistance[43–46].

Lastly, Incident to photon current conversion efficiency (IPCE) is the ratio of the photo-generated electrons ($N_{\text{electrons}}$) flowing through the external circuit to the incident photons (N_{photons}) at a given wavelength which is described in (Equation 4).

$$\text{IPCE}(\lambda) = \frac{N_{\text{electrons}}(\lambda)}{N_{\text{photons}}(\lambda)} \quad (4)$$

This measurement gives information regarding how much the DSSCs convert incident photons to electrons at a given wavelength. A high IPCE value corresponds to increased DSSCs conversion

efficiencies of the photons to electrons hence a better yield. This can further be evaluated using (Equation 5)[47–49].

$$\text{IPCE}(\lambda) = \text{LHE}(\lambda) \eta_{\text{inj}}(\lambda) \eta_{\text{col}}(\lambda) \quad (5)$$

Where LHE, the light-harvesting efficiency, η_{inj} is the quantum yield of the electron injection and η_{col} is the charge collection efficiency.

Using IPCE measurement the mesoporous photo anode has better efficiency due to its ability to highly collect charge carriers and favorable photodegradation.

3. Characterization techniques of photoanodes in DSSCs.

The methods that are used to understand the crystal orientation, morphology, surface functional groups, surface area, elemental composition, and other physical and chemical properties of the nanomaterials are termed Characterization techniques[50]. The commonly used characterization techniques include X-ray Diffraction (XRD)[51], Scanning Electron Microscopy(SEM),X-ray Photoelectron Spectroscopy (XPS) [52], Transmission Electron Spectroscopy(TEM)[53], Scanning Transmission Electron microscopy(STEM)[54], Raman Spectroscopy[55], Thermogravimetric Analysis(TGA)[56], UV-visible Spectroscopy[57], Brunauer-Emmett-Teller (BET)[58] and Fourier Transform Infrared Spectroscopy (FTIR)[59].

Scanning Electron Microscopy (SEM) is a characterization technique that is used to determine the morphology and composition of a given material. A high-energy electron beam is used to scan the nanomaterials and the magnified image is formed through mapping signal intensity and scan rate [60, 61]. Yao et al[62] carried out SEM analysis on Carbon nanofibers@TiO₂ nanoparticles to analyze the morphology as shown in Figure 5.

Figure 5. SEM image (a) carbon nanofibers and (b) TiO₂ nanoparticles@ carbon nanofibers. Reprinted with permission ref[62]. Copyright 2019, Elsevier.

The carbon nanofibers with a diameter of 600 nm are observed to have a smooth surface which is revealed in Figure (a). Figure (b) shows the morphology of TiO₂ nanoparticles@ carbon nanofibers which TiO₂ forms clusters on the surface which makes it rough but also their a reduction in the diameter (300 nm) of the TiO₂ nanoparticles@ carbon nanofibers composite. Transmission Electron microscopy (TEM) is a technique used to understand the inside of a material with great detail due to its high resolution and ability to even show small interactions between nanoparticles and their constituents. It has a small wavelength hence able to produce images in the sub-nanometer resolution with enough energy that can easily penetrate even very small crystals. Li et al[63] used TEM analysis (Figure 6) to determine the interaction and compatibility of TiO₂ nanoparticles and carbon nanotubes.

Figure 6. TEM image of Titanium dioxide particles and carbon nanotubes. Reprinted with permission ref[63]. Copyright 2020, Elsevier.

The TiO_2 nanoparticle (5-10 nm) agglomerate to form clusters and are uniformly distributed on the surface of the carbon nanotubes hence the formation of heterostructures as shown in Figure 6 (d-f).

Scanning Transmission Electron microscopy (STEM) is a technique used to determine the site-specific analysis of an image's resolution in the nanometer and sub-nanometer range. During this characterization, a dark field STEM image or bright field STEM picture can be formed basing on the transmitted electrons used during the formation of the image. Zhu et al [64] used Titanium dioxide nanofibers@ SnO_2 nanocubes as photoanode for dye sensitized solar cells Figure 7.

Figure 7. STEM image of the nanofibers and the corresponding EDS mapping of Sn, Ti, and O [64].

The scanning transmission electron microscopy shows an image and the corresponding EDS mapping for Sn, Ti, and O. It is observed that Sn and O have broader distributions compared to

Ti and further gives information about the SnO₂ nanocubes which are connected to the TiO₂ nanofibers.

X-ray diffraction (XRD) is one of the most applied characterization techniques when it comes to structural determination of nanomaterials during DSSCs fabrication. Its working principle is based on Bragg's law and X-rays from monochromatic light. Diffraction of the x-ray from the crystal structure of the material depends on the interplanar distance, scattering angle, and wavelength as shown in (Equation 6).

$$2d \sin \theta = n\lambda \quad (6)$$

Where d is the lattice spacing, θ represents the incident angle, λ is the wavelength, and n is the diffraction order. This technique gives information regarding the crystallinity of the material i.e. high peaks represent highly crystalline surfaces while broad peaks describe amorphous surfaces which are then compared with the International Centre for Diffraction Data (ICDD). Ahmad et al[65] used XRD analysis (Figure 8) to determine the crystalline structure of titanium dioxide nanoparticles.

Figure 8. XRD spectra of TiO₂ nanoparticles containing Anatase and Rutile phases[65].

The 2θ were observed at 25.33, 36.01, 37.90, 48.06, 53.96, 55.06, 62.70, 69.01, and 70.41° which correspond to planes (101), (103), (004), (200), (105), (211), (204), (116) and (200) which mainly describe the anatase and rutile phase. From this analysis, the (101) plane had the strongest diffraction peak at 25.33° which is due to the Anatase form which is the most dominant in the titanium dioxide. The rutile form was also observed at 53.96 and 55.06°.

X-ray Photoelectron spectroscopy (XPS) uses x-rays to stimulate photoelectrons that determine surface depths upto about 10nm. This technique has been observed to determine bigger particles within 100 nm. Khalid et al [66] used XPS analysis (Figure 9) to determine the electronic structure, valence states, and bonding properties of titanium dioxide nanoparticles.

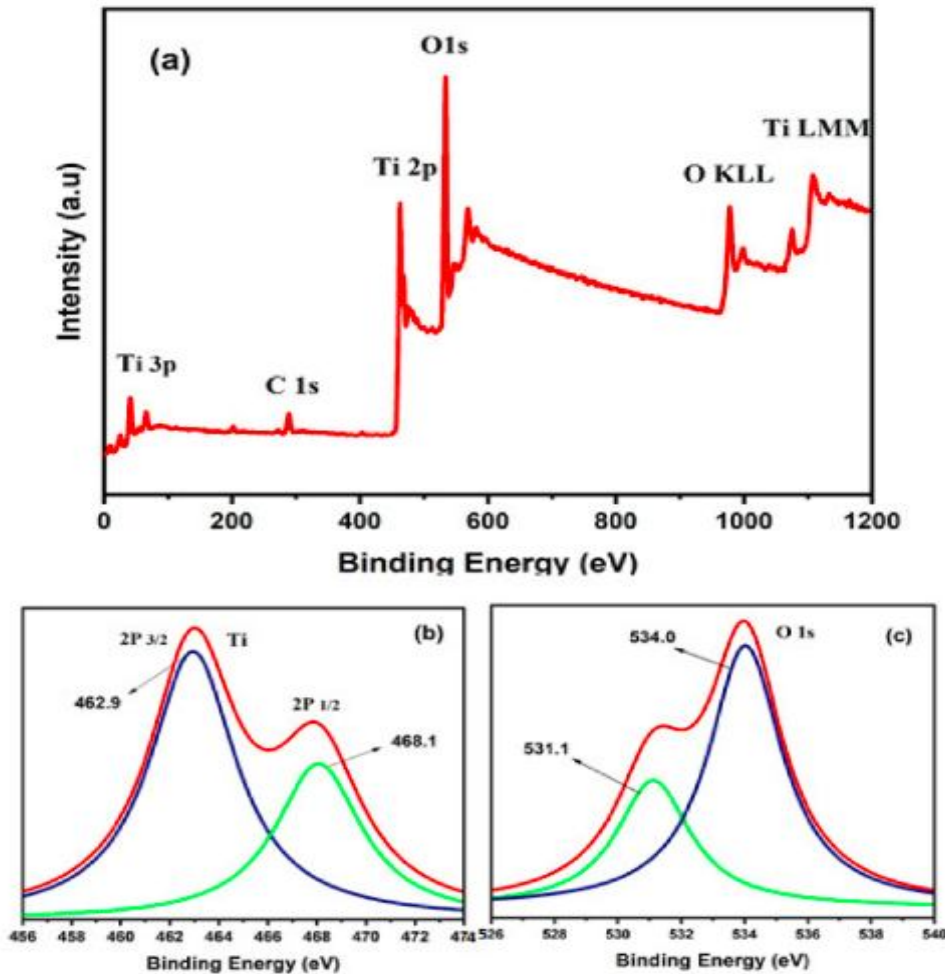

Figure 9. XPS analysis of Titanium dioxide nanoparticles [66].

The Ti 2p and O 1s are observed with no contamination but the C 1s are also observed at 285 eV[67]. The binding energy of the elements is determined and the spin states of Ti 2p_{3/2} and Ti 2p_{1/2} at binding energies of 463 eV and 468 eV for Ti⁴⁺ in TiO₂ are also determined which explains that Ti exists in the same oxidation state [68].

Fourier Transform Infrared Spectroscopy (FTIR) is another characterization technique that is used to determine the surface functional groups and optical properties of a variety of samples in the spectral region which ranges from 4000 – 400 cm⁻¹. Nanomaterials have atoms that vibrate at frequencies that are within the spectral range of FTIR. Guan et al[69] analyzed pure TiO₂ and TiO₂@Ni nanocomposite using FTIR is used to determine the surface functional groups (Figure 10). The bands at 662 and 704 cm⁻¹ are characteristic of Ti-O vibrations in the lattice structure of TiO₂. A broad band in the region between 3000-3500 cm⁻¹ is due to the surface hydroxyl groups and the stretching vibration on the TiO₂ surface but also a band around 1000-1700 cm⁻¹ is due to the water molecule (H-O-H) with bending vibrations[70]. Ti-O-Ti vibrations are also observed with a broad band in the region of 1000-1200 cm⁻¹.

Figure 10. FTIR spectrum of a) TiO₂ nanoparticles and b) TiO₂-Ni nanocomposite [69].

Brunauer-Emmett-Teller (BET) analysis is used on the principle of physio-sorption of gas on a solid surface to determine the pore volume, surface area, and pore size of different materials. The gas that is normally used for the desorption and adsorption on solid surfaces is Nitrogen. This technique is considered a modification of the Langmuir adsorption as it considers multiple layer adsorption. Pai et al[71] analyzed TiO₂ nanoparticles using BET as shown in Figure 11. The surface area of the nanoparticles was estimated to be 86 m² g⁻¹, the pore volume was 0.46 cm³ g⁻¹ and the pore size was about 212 Å which parameters aid in dye absorption onto the semiconductor.

Figure 11. Nitrogen desorption-adsorption isotherm of TiO₂ showing the pore volume insert [71].

TGA is a technique that is used to determine the composition, thermal stability, decomposition, kinetics of chemical reactions, and evaporation behavior of a material when varying temperature is applied. Bekele et al[72] analyzed TiO₂ nanoparticles for their stability and energy absorption using Thermal Gravimetric-Differential Thermal Analysis (TGA-DTA) Figure 12. The TGA curve shows the weight loss of the TiO₂ nanoparticles while the DTA curve shows the energy gain or loss during the whole process. The weight loss at 150 °C is mainly due to the loss of water molecules, 350 °C is due to carbonization and pyrolysis of biomass. Further at 483 °C the

weight loss corresponds to strong DTA peaks due to vaporization of residues and at 500 °C no weight loss was observed and this is taken as the carbonization temperature.

Figure 12. TGA/DSC analysis of TiO₂ nanoparticles [72].

RAMAN is a technique that uses vibrational modes to determine the phase, polymorphy, crystallinity, chemical structure, and molecular interactions of a sample which occurs when light from the laser interacts with the material's chemical bonds. Khalid et al[66] studied the spectrum of titanium dioxide nanoparticles using Raman spectroscopy as shown in Figure 13.

Figure 13. Raman spectrum of Titanium dioxide nanoparticles [66].

It shows B_{1g} , ($A_{1g} + B_{1g}$), and E_g peaks at 399, 516, and 637 cm^{-1} [73, 74]. The vibrational modes in TiO_2 are caused by bending, asymmetric, and symmetric vibrations of the Ti-O-TiO bond [75, 76]. The B_{1g} peak corresponds to Ti-O bending mode where the Ti-O-Ti (Ti is moving), $A_{1g} + B_{1g}$ Ti-O stretching mode (O is moving) and E_g is the Ti-O stretching mode [77].

UV-VIS is used to measure the optical spectral properties of materials through light absorption of samples that are in solution. Using Beer Lambert's law this characterization technique gives information regarding the concentration and composition of a sample. It is also easy to operate, cheap, and does not destruct the sample after analysis. Camposeco et al [78] used UV-Vis spectroscopy to study the optical properties of different Titanium dioxide nanostructures as shown in Figure 14.

Figure 14. UV-Vis spectrum of nanoparticles, nanotubes, nanofibers, nanowires, and P-25. Reprinted with permission ref [78]. Copyright 2016, Elsevier.

It is observed that the anatase form of titanium dioxide has an absorption of 380-459 nm with an energy band gap (E_g) of 3.2 eV. The nanotubes have an observable red shift towards the visible light region of the spectrum which is mainly attributed to the synthesis method and

temperature[79]. Insert Figure UV-Vis spectra showed the energy band gap (eV) of the nanoparticles (3.18), nanofibers (3.10), nanotubes (3.0), and nanowires (3.09).

4. TiO₂nanofibers, nanowires, nanotubes, nanoparticles, and their application in DSSCs

Titanium dioxide is known to exhibit four polymorphic forms which include anatase, rutile, brookite, and TiO₂ (B)[80]. It also has other polymorphs that are metastable such as perovskite, TiO₂ II, and TiO₂ (H) which are normally synthesized using synthetical pathways that require certain conditions. The most stable form is rutile while anatase and brookite are known to transform to rutile at high temperature conditions which also affects titanium nanostructure formation[81, 82]. Figure 15 shows the crystal forms of the unit cells of the four most common titanium dioxide polymorphs[83].

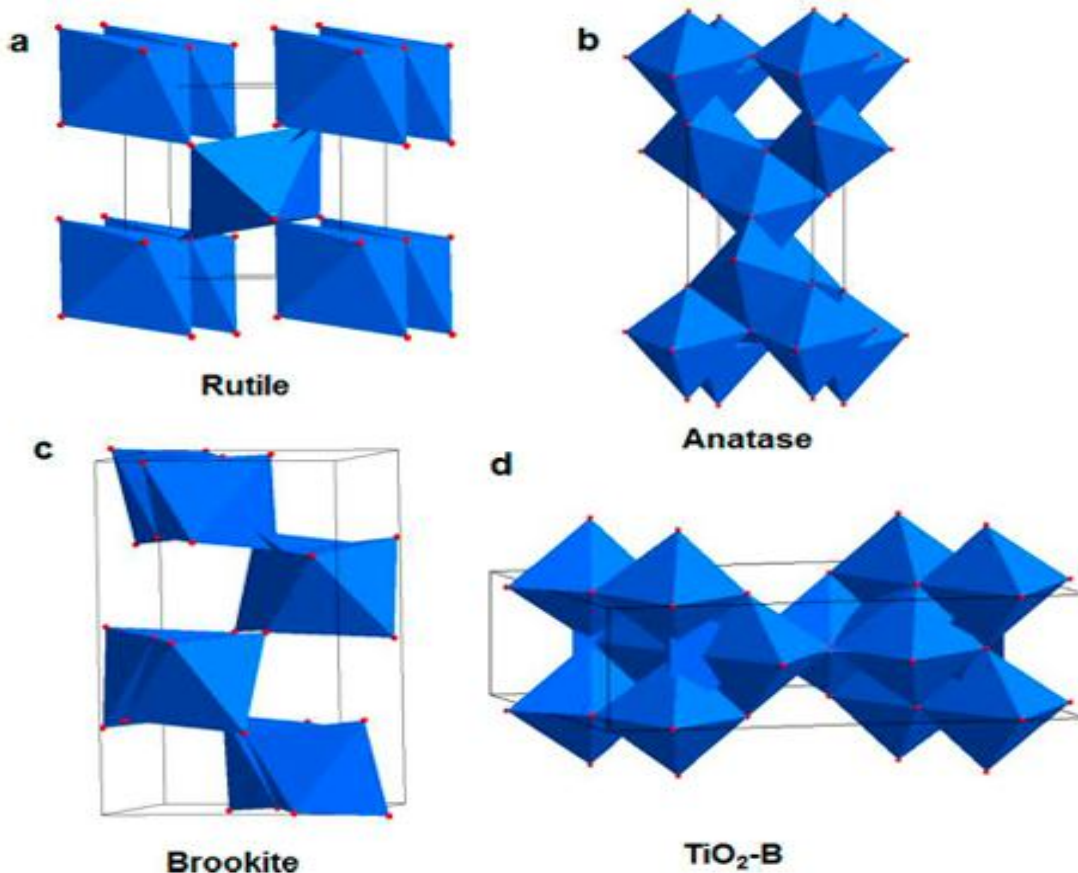

Figure 15. A schematic unit cell of titanium dioxide crystal forms (a) Rutile, (b) Anatase, (c) Brookite, and (d) TiO₂ B)[83].

The Ti-O octahedron is known to be the fundamental building block of all the four crystal forms of TiO₂ which influences its symmetry. The nanostructures of these polymorphs tend to exhibit different morphologies and growth behaviors. Rutile has a tetragonal structure with a-axis (0.459 nm) and c-axis (0.296 nm), anatase also has a tetragonal structure with a-axis (0.379 nm) and c-axis (0.951 nm). Brookite has 8 TiO₂ groups containing large cell units which results in an orthorhombic structure. TiO₂ B has a monoclinic structure which is more open with large cell units and consists of long a-axis (1.216 nm)[84]. Table 1 shows the detailed structural parameters of Rutile, Brookite, and Anatase[85].

Table 1. Structural parameters of the crystal forms of Titanium dioxide[85].

Parameter	Rutile	Brookite	Anatase
Unit cell	2	4	8
Atomic spacing (Å)	a = 4.596 c = 2.958	a = 9.184 b = 5.447 c = 5.145	a = 3.784 c = 9.515
Density (g/cm ³)	4.13	3.99	3.79
Bond Length Ti-O (Å)	1.949 (4) 1.980 (2)	1.87-2.04	1.937 (4) 1.965 (2)
Bond Angle O-Ti-O (Å)	81.2° 90.0°	77.0-105°	77.7° 92.6°

Titanium dioxide is synthesized using a number of techniques such as hydrothermal treatment, chemical, and physical vapor deposition, sputtering, sonochemical, template method, pulse laser ablation, electrodeposition, sol-gel, micro-emulsion, etc[86–89]. Synthesis of the nanomaterials is based on a number of precursors such as titanium tetrachloride (TiCl₄), titanium alkoxide, titanium isopropoxide (TTIP), titanium trichloride (TiCl₃) and titanium tetrabutoxide (TBT)[90–92].

A number of Titanium dioxide nanomaterials such as 0D, 1D, 2D, and 3D architectures have been applied to determine their influence on the conversion efficiency of the dye sensitized solar cells as shown in Figure 16[93].

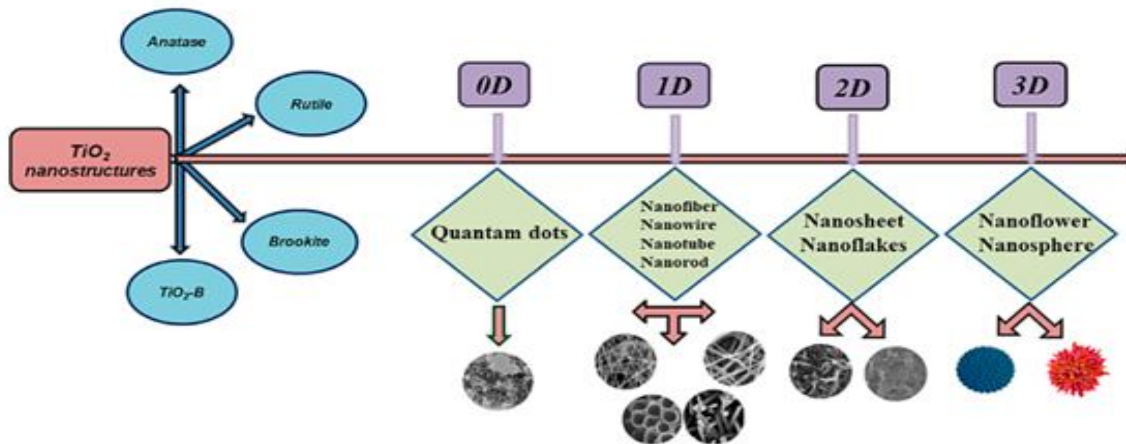

Figure 16. Titanium dioxide nanostructures and the different dimensions[93].

The 0D nanostructures have a sphere or quasi sphere shape and have diameters less than 100 nm. They have a high surface to volume ratio, less toxic, high quantum yield, and a number of active sites per unit mass[94]. The common members are the noble metal nanoparticles[95], carbon quantum dots[96], polymer dots[97], graphene quantum dots[98], and the fullerenes[99].

In addition, the 1D nanostructures have a high length to diameter ratio which improves the chemical, magnetic, and mechanical properties of the materials. They also have a large surface area, highly uniform, crystalline, and hollow which all enable their application in energy devices[100, 101]. They include nanowires, nanotubes, nanorods, and nanofibers.

Furthermore, the 2D nanostructures whose atom layer thick planar structures are each bonded using weak van der waal forces[102]. The in plane covalent nature of the 2D structures leads to its robust nature and good mechanical stability[103]. The nanosheets[104] and nanoflakes[105] belong to this group of nanostructures.

Lastly the the 3D nanostructures whose organization, arrangement, and formation are developed using the 0D, 1D, and 2D materials whose morphologies are achieved based on the growth conditions. Among the 3D nanostructures, popular examples include nanoflowers[106], nanospheres[107], nanocubes[108], nanocages[109], dendrimers[110], and fullerenes[111].

The 1D architectures have found wide application in dye sensitized solar due to their large surface area, good electronic properties, ease of fabrication, good chemical stability, and high aspect ratio as shown in Table 2[93, 112].

Table 2. One dimensional structures and the commonly used synthesis techniques.

1D TiO₂ Nanostructures	Synthesis Technique
Nanotubes (NTs)	Electrochemical deposition, sol-gel, hydrothermal
Nanowires (NWs)	Solvothermal, microwave-assisted, sol-gel, hydrothermal
Nanorods (NRs)	Sol-gel template, hydrothermal, chemical vapor deposition
Nanofibers (NFs)	Hydrolysis, hydrothermal, electrospinning + sol-gel

Titanium dioxide nanowires are the most applied 1D nanostructures in dye sensitized solar cells due to their large surface area which favors dye loading and anchorage. Table 3 shows Titanium dioxide nanowires, their composites, and how they influence DSSCs performance.

Table 3. Performance of titanium dioxide nanowires and nanocomposite photoanodes.

Electrode	J_{sc} (mA/cm²)	V_{oc} (V)	η (%)	FF	Reference
TiO ₂ NWs	17.38	0.687	8.90	0.75	[113]
Sn-TiO ₂	15.84	0.755	8.75	0.73	[114]
TiO ₂ NWs/TiO ₂ NPs	14.02	0.762	7.92	0.74	[115]
TiO ₂ NWs-RGO	10.41	0.714	4.95	0.67	[116]

H. Li et al [113] synthesized pure Titanium dioxide nanowires as photoanodes for DSSCs and obtained an efficiency of 8.90 %. This is attributed to the high J_{sc} (17.38mA/cm²) which enables high light scattering and harvesting but also improves dye loading. Makal & Das [116] synthesized Reduced graphene oxide/Titanium dioxide nanowires as photoanodes and obtained an efficiency of 4.95 % which is lower than pure TiO₂(8.90 %) due to a lower J_{sc} 10.41mA/cm². Reduced graphene oxide increases the rate of electron transfer but also inhibits the electron-hole charge carrier recombination. Another group of Ni et al [114] synthesized Titanium dioxide doped Sn nanowires as photoanodes for DSSCs and the conversion efficiency was 8.75 %. The high J_{sc} increases the light harvesting ability of the photoanode[117]. Wu et al [115] synthesized Titanium dioxide nanowires-Titanium dioxide nanoparticles as photoanodes for DSSCs and the efficiency obtained was 7.92 %. This is attributed to the high J_{sc} 14.02mA/cm² which improves the light scattering ability but also on the dye loading onto the photoanode.

Titanium dioxide nanoparticles were studied to understand their effect on the overall performance of the DSSCs. Table 4 shows the photochemical parameters of TiO₂, TiO₂/rGO, TiO₂ (NRs/NP), Cu-TiO₂NP-Graphene and TiO₂ NP/ZnO Nanorod.

Table 4. Performance of titanium dioxide nanoparticle and nanocomposite photoanodes.

Electrode	J _{sc} (mA/cm ²)	V _{oc} (V)	η (%)	FF	Reference
TiO ₂	9.68	0.732	9.34	0.70	[118]
TiO ₂ /rGO	12.57	0.761	6.64	0.54	[119]
TiO ₂ (NRs/NP)	17.22	0.690	8.61	0.72	[120]
Cu-TiO ₂ NP-Graphene	19.93	0.745	9.81	0.66	[121]
TiO ₂ NP/ZnO Nanorod	14.20	0.704	6.50	0.65	[122]

Dhonde et al[121] demonstrated the use of Cu-TiO₂NP-Graphene as photoanodes and they showed a conversion efficiency of 9.81 % comparable to that of TiO₂ (9.34 %). This is because Cu doping improves on V_{oc} but also reduces the energy band gap of TiO₂[123, 124]. In addition, graphene improves the J_{sc} as it improves dye loading, charge separation, electron mobility and reduces the charge carrier recombination[125]. Furthermore, Chatterjee et al[120] used TiO₂ (NR/NP) as photoanodes for DSSCs and the conversion efficiency was 8.61% which is also comparable to that of TiO₂. This is because the nanorod-nanoparticle composite increases the J_{sc} of the DSSCs through improvement in the dye loading and light scattering which increases the efficiency [126]. Further studies by Zatirostami[122] demonstrated the use of TiO₂ NP/ZnO Nanorod and the conversion efficiency was 6.50 % which is comparable to TiO₂ (9.34 %). This was due to the hierarchical structure of the ZnO nanorods but also the high porosity of TiO₂ nanoparticles which improved dye loading, light scattering, and diffusion of the electrolyte into the semiconductor.

Nanotubes have also been studied in the determination of the conversion efficiency and performance of dye sensitized solar cells. The Titanium dioxide nanotubes and their composites have shown great application as photoanodes in DSSCs application with relatively high efficiencies as shown in Table 5.

Table 5. Performance of titanium dioxide nanotubes and nanocomposite photoanodes.

Electrode	J_{sc} (mA/cm ²)	V_{oc} (V)	η (%)	FF	Reference
TiO ₂ TNTs	18.41	0.69	8.19	0.64	[127]
N-TiO ₂ NTs	19.29	0.70	7.36	0.55	[128]
TNT/rGO	10.70	0.78	5.33	0.64	[129]
Ag-TNTs	17.26	0.78	7.20	0.54	[130]
Cr-TNTs	26.29	0.69	11.05	0.61	[127]

Nguyen et al[127] used Cr-TNTs as photoanodes and the conversion efficiency was 11.05 % which is higher than that of the undoped TiO₂ nanotubes. This is because of the high J_{sc} (26.29mA/cm²) which is due to the heterostructure of the TiO₂ nanotubes that causes a high dye loading ability [131, 132]. The oxygen vacancy sites due to doping cause the creation of holes which reduce the charge recombination. The Cr³⁺ and Ti³⁺ can also become defect centers in which they end up holding dye molecules on the composite which further influences the efficiency. In addition, Tran et al[128] used N-TiO₂ NTs as photoanodes and the conversion efficiency was 7.36 % which is comparable to that of undoped TiO₂ (8.19 %). This is also due to the increase in J_{sc} (19.29mA/cm²) which is a result of high electron injection into the reduced conduction band of the semiconductor but also the reduction in the electrolyte charge recombination [133].

Lastly, the Nanofibers have been applied as photoanodes in dye sensitized solar cells. Table 6 shows some of the Titanium dioxide nanofibers that have shown good conversion efficiencies when used as photoanodes.

Table 6. Performance of titanium dioxide nanofibers and nanocomposite photoanodes.

Electrode	J_{sc} (mA/cm ²)	V_{oc} (V)	η (%)	FF	Reference
TiO ₂ NFs	9.70	0.812	5.1	0.65	[134]
Ag NPs-TiO ₂ NFs	11.24	0.789	6.19	0.69	[135]
GO-TiO ₂ NFs	9.41	0.784	4.52	0.61	[136]
SnO ₂ -TiO ₂	17.00	0.732	8.0	0.64	[134]
TiO ₂ NFs/TiO ₂ NPs	14.46	0.750	7.13	0.65	[137]

Bakr et al[134] used SnO₂-TiO₂ as photoanodes and the conversion efficiency was 8.0 % which is slightly higher than that of bare TiO₂ nanofibers (5.1 %). This is because of the high J_{sc} (17.00mA/cm²) which is due to the SnO₂ network which improved the surface area, electron transport, and dye loading onto the nanofibers. In addition, Vu et al[137] used TiO₂ NFs/TiO₂ NPs as photo anodes during DSSCs study and the efficiency was 7.13 % which is higher than that of TiO₂ (5.1 %). This is because of the increased J_{sc} (14.46mA/cm²) which is due to the improved light harvesting and scattering ability of the Titanium dioxide nanofibers [138].

5. Conclusion

Dye sensitized solar cells convert solar to electric energy through the use of different components including the photoanode. It functions as an anchorage onto which the dye sensitizer is attached but also transfers electrons to the external circuit. The efficiency of the photoanode as observed is greatly affected by the short circuit current (J_{sc}) that is an increase in J_{sc} leads to a high efficiency. Titanium dioxide nanostructures are commonly used photoanode in dye sensitized solar cells due to their large surface area which improves dye loading and the overall efficiency (12 %). Titanium dioxide nanowires, nanotubes, nanoflowers, nanoribbons, nano-onions, nanoflakes, and nanofibers are used as photoanodes achieving efficiencies that are comparable to nanoparticles (12 %). The titanium nanotubes are observed to have high efficiencies of 11.05 % which are mainly due to their heterostructure and large surface area which allows dye loading and electron transfer. The nanowires also offer high efficiencies of 8.90 % which is also due to the large surface area for dye loading and photon absorption and scattering. Furthermore, the nanofibers with efficiencies of 8.0 % which are accounted for by the high J_{sc} values, and dye loading have seen a rapid growth. Lastly, the characterization of these nanostructures has been reviewed using a number of techniques to understand the crystal orientation, morphology, surface functional groups, surface area, elemental composition, and other physical and chemical properties. In brief, this review confirms that the nanotubes, nanofibers, and nanowires are ideal candidates to be applied as photoanodes in DSSCs devices.
