# Potassium Fractions and Release from Mineral Sources of Potassium as Influenced by Potassium Solubilizing Bacteria (*Bacillus sporothermodurans*)

## ABSTRACT

Potassium (K) in soil exists in four different forms such as water soluble, available, exchangeable and non-exchangeable potassium. Variation in K fractions in soils through addition of different mineral sources of K is essential to determine suitable mineral source for crops. A laboratory incubation study was conducted using seven mineral sources of K such as sulphate of potash, langbeinite, sylvinite, kainite, patentkali, glauconite and rockdust for a period of 180 days to evaluate the release pattern of different K fractions with and without adding potassium solubilizing bacteria (*Bacillus sporothermodurans*). The results revealed that potassium fractions varied significantly with the mineral sources. The water soluble and available K were increased gradually while non-exchangeable potassium showed a gradual decrease in content when potassium solubilizing bacteria added. But there was decrease in these fractions from 120 days of incubation when mineral sources alone were added. The highest water soluble and available potassium recorded in treatment received sulphate of potash and langbeinite with and without potassium solubilizing bacteria. The water soluble content in the soil samples varied from 86.00 kg ha<sup>-1</sup> to 268.90 kg ha<sup>-1</sup> and available K ranged in between 144.60 kg ha<sup>-1</sup> to 326.75 kg ha<sup>-1</sup>. The exchangeable K content ranged from 45.20 kg ha<sup>-1</sup> to 137.40 kg ha<sup>-1</sup> and the highest content was recorded by treatment received sylvinite. Non-exchangeable K content was ranged from 59.95 kg ha<sup>-1</sup> to 221.10 kg ha<sup>-1</sup>. When analysing the release of K from mineral sources it can be concluded that sulphate of potash and langbeinite having more available form of K whereas sylvinite contain more K as exchangeable form. In rock dust and glauconite non-exchangeable form of K was dominating. Potassium solubilizing bacteria converted the non-exchangeable form to available form in all mineral sources of K.

*Keywords: Potassium fractions, release, mineral sources, water soluble K, available K, exchangeable K, Non-exchangeable K, potassium solubilizing bacteria.*

## 1. INTRODUCTION

Potassium is an essential, major plant nutrient with numerous functions of activating about sixty enzymes, regulating stomatal function, controlling water relations especially under rainfed crop production, influencing the water balance of the plant system, and underpinning agronomic productivity and sustainability<sup>[6]</sup>. K is also the most abundant nutrient element in the earth's crust and it accounts for 2.6 per cent of the weight of earth's crust which is more than phosphorus which weighs only 0.1 per cent and nitrogen is only present in trace amounts<sup>[9]</sup>.

Plants often absorb a large amount of potassium equal to or greater than nitrogen, which has drawn attention to study the behaviour of potassium in soil. Usually nitrogen and phosphorus are more concerned than K which is an important nutrient determining the yield of a crop. A thorough understanding of potassium status in the soil could be possible only by measurement of its different forms in the soil solution and the solid phase of soil.

Potassium exist in soil in different forms viz., water soluble, available, exchangeable, and non-exchangeable K. But these forms were not homogeneously distributed in soils. Its amount in soil depends on the parent material, degree of weathering, K gains through manures and fertilizers and losses due to crop removal, erosion and leaching. As rocks break down into sand, silt and clay, that will enrich the soil with potassium and other nutrient elements by releasing and became available to plants. Water soluble K is directly taken up by plants and microbes which is most subjected to leaching loss. The content of water soluble K is generally low, unless external source of K have been added to the soil. Exchangeable K is the portion of the soil K that is electrostatically bound as an outersphere complex to the surfaces of clay minerals and humic substances. It is readily exchanged with other cations and also available to plants. Non-exchangeable K is held between adjacent tetrahedral layers of dioctahedral and trioctahedral micas, vermiculites and intergraded clay minerals such as chloritized vermiculite. There is one more form of K that is mineral potassium in which K bonded within the crystal structure of K-bearing primary minerals such as muscovite, biotite and feldspars<sup>[16]</sup>.

Under conventional cropping systems, a large amount of K is being removed, leading to serious depletion of soil K reserves<sup>[11]</sup>. In order to overcome the problem of K deficiency in soil, supplementing external input during crop cultivation is necessary with mineral sources of potassium like glauconite, sulphate of potash (SOP), langbeinite, sylvinite, patenkali and kainite<sup>[7]</sup> which are capable of meeting the potassium requirement of crops and are potential sources K especially under organic cultivation. Glauconite is a micaceous mineral containing K, Fe and Mg, as well as Al and Si and the chemical formula is  $(K, Na)(Fe(III), Al, Mg)_2(SiAl)_4O_{10}(OH)_2$ <sup>[17]</sup>. SOP is generally contains K (40 per cent) and S (17 per cent). Langbeinite is a potassium magnesium sulphate mineral with the chemical formula  $K_2Mg_2(SO_4)_3$ . It provides a readily available supply of potassium (K), magnesium (Mg) and sulphur (S). Sylvinite is a sedimentary rock made of a mechanical mixture of the minerals sylvite (KCl or potassium chloride) and halite (NaCl or sodium chloride). Patentkali is chemically sulphate of potash containing magnesium salt having 30 per cent  $K_2O$ , 10 per cent MgO and 42.5 per cent  $SO_3$ <sup>[18]</sup>. Kainite is one of the naturally occurring sources of potassium. It is a double salt of hydrated potassium and magnesium sulphate chloride ( $KMgSO_4Cl \cdot 3H_2O$ ).

Potassium solubilizing microbes (KSM) is a group of micro-organisms playing a key role in the natural K cycle. It solubilizes the unavailable form of K into available form of K through mechanisms such as acidolysis, chelation, complexolysis, exchange reactions and production of organic acids<sup>[5]</sup>. In soil the amounts of non-exchangeable K present are high as compared to water soluble and exchangeable K<sup>[13]</sup>. The application of KSM is effective in utilization of the unavailable forms of K such as non-exchangeable K. Hence a study was conducted to evaluate the release pattern of various K fractions in soil when applied with the organic mineral sources alone and along with KSM.

## 2. MATERIALS AND METHODS

A laboratory incubation experiment was conducted in College of Agriculture, Vellayani, Thiruvananthapuram, Kerala Agricultural University during 2020-21 to study the potassium release pattern from mineral sources of K alone and with potassium solubilizing bacteria (*Bacillus sporothermodurans*). The selected mineral sources of K were sulphate of potash,

patentkali, sylvinite, langbeinite, kainite, glauconite and rock dust. Five kilograms of soil was taken in pots and the selected organic mineral potassium sources were added to the pots by thorough mixing at the rate of 75 Kg K<sub>2</sub>O per ha. The moisture in pots was maintained at field capacity. The study was laid out in completely randomized design (CRD) with fifteen treatments and two replications *viz.*, soil alone (T<sub>0</sub>), sulphate of potash 75 kg ha<sup>-1</sup> + 5 kg soil (T<sub>1</sub>), patentkali 75 kg ha<sup>-1</sup> + 5 kg soil (T<sub>2</sub>), sylvinite 75 kg ha<sup>-1</sup> + 5 kg soil (T<sub>3</sub>), langbeinite 75 kg ha<sup>-1</sup> + 5 kg soil (T<sub>4</sub>), kainite 75 kg ha<sup>-1</sup> + 5 kg soil (T<sub>5</sub>), glauconite 75 kg ha<sup>-1</sup> + 5 kg soil (T<sub>6</sub>), rock dust 75 kg ha<sup>-1</sup> + 5 kg soil (T<sub>7</sub>), sulphate of potash 75 kg ha<sup>-1</sup> + 5 kg soil + potash solubilizing bacteria 2kg ha<sup>-1</sup> (T<sub>8</sub>), patentkali 75 kg ha<sup>-1</sup> + 5 kg soil + potash solubilizing bacteria 2kg ha<sup>-1</sup> (T<sub>9</sub>), sylvinite 75 kg ha<sup>-1</sup> + 5 kg soil + potash solubilizing bacteria 2kg ha<sup>-1</sup> (T<sub>10</sub>), langbeinite 75 kg ha<sup>-1</sup> + 5 kg soil + potash solubilizing bacteria 2kg ha<sup>-1</sup> (T<sub>11</sub>), kainite 75 kg ha<sup>-1</sup> + 5 kg soil + potash solubilizing bacteria 2kg ha<sup>-1</sup> (T<sub>12</sub>), glauconite 75 kg ha<sup>-1</sup> + 5 kg soil + potash solubilizing bacteria 2kg ha<sup>-1</sup> (T<sub>13</sub>), rock dust 75 kg ha<sup>-1</sup> + 5 kg soil + potash solubilizing bacteria 2kg ha<sup>-1</sup> (T<sub>14</sub>).

Soil samples were collected from the pots on 0, 15, 30, 45, 60, 90, 120, 150 and 180 days after application of treatments, air dried in shade, ground using wooden pestle and mortar and sieved through 2 mm sieve and analysed for K fractions *viz.*: Water soluble K, available K, Exchangeable K, HNO<sub>3</sub> extractable K and non-exchangeable K.

Water soluble K was estimated by extraction with distilled water (Soil water ratio 1:5) and the potassium in the extract was determined by flame photometer [3]. Available K was determined by extracting soil with neutral normal ammonium acetate solution (1 N) in a ratio of 1:2.5 and K content in the extract was determined by flame photometry [3]. Exchangeable K was computed as the difference between available K and water soluble K. The boiling 1N HNO<sub>3</sub> method [14] was followed for the determination of HNO<sub>3</sub> extractable K in soil. The soil acid ratio is 1:10 and the potassium content in the extract was determined using flame photometer. Non-exchangeable K was estimated by subtracting available K from HNO<sub>3</sub> extractable K.

## RESULTS AND DISCUSSIONS

### 3.1 Water soluble K

The water soluble K content (Table 1) varied from 22.85 to 268.90 kg ha<sup>-1</sup> from 0 day to 180 days of incubation. The highest amount of K was released in treatments T<sub>8</sub> (268.90 kg ha<sup>-1</sup>) and T<sub>1</sub> (248.25 kg ha<sup>-1</sup>) which received sulphate of potash along with KSB and SOP application only at 180<sup>th</sup> and 120<sup>th</sup> day of observations respectively. The release of water soluble K was found to increase in all treatments up to 120 days. After 120 days the treatments which received the minerals alone were found to decrease the water soluble K content except glauconite and rock dust. In the case of glauconite and rock dust an increase was found up to 150 days and then decreased. Application of mineral sources along with the KSB gradually increased the water soluble K content up to 180 days of incubation.

The increased release of water soluble K fraction may be due to the increased solubility of all the minerals in water. The water soluble K content in soil depends on the moisture content and its concentration found maximum at field capacity [12]. Above field capacity the K ions may be subjected to leaching. A decrease in the K content in the treatments receiving minerals alone was recorded after 120 days of incubation. This may be due to the reversible reaction occurring to maintain the equilibrium between the K fractions. All the K forms in the soil are in dynamic equilibrium with each other that affects the level of water soluble K [10]. A gradual increase of water soluble K observed in treatments receiving minerals along with KSB throughout the incubation period. This may be due to the activity of the K solubilizing microbes in the inoculum which quickly dissolve minerals and chelate silicon ions, releasing K ions into the soil to make potassium available from unavailable forms [2].

### 3.2 Available K

The available K content (Table 2) was increasing gradually up to 90 days and thereafter a decrease in available K content was observed in treatments receiving minerals alone. The highest available K was recorded by the treatment T<sub>8</sub> (326.75 kg ha<sup>-1</sup>) which received SOP along with KSB and the lowest content was recorded by kainite (144.60 kg ha<sup>-1</sup>) at 1<sup>st</sup> day of incubation. The pattern of K release from the mineral sources indicating that, sulphate of potash released the available K rapidly into the soil followed by

langbeinite. Treatment T<sub>8</sub> had the highest K content throughout the incubation period followed by T<sub>1</sub> (SOP), T<sub>4</sub> (langbeinite) and T<sub>11</sub> (langbeinite+KSB). Sylvinite, patentkali and kainite were released K relatively slow when compared to SOP and langbeinite even though they were having more K content. Glauconite and rock dust were also released K very slowly.

The increase in available K observed would be due to the fraction that contributed by the release of K<sup>+</sup> ions from the K minerals as well as the soil clay minerals. The water soluble fraction from K mineral, if it was neither

absorbed by the plant nor subjected to leaching get converted into exchangeable form. These could be the reasons for increase in available K at initial stages [4]. In treatments receiving K minerals along with KSB showed an increase in available K may be due to the presence of K solubilizing microbes which play a key role in the natural K cycle. It solubilizes the unavailable form of K (i.e., Non-exchangeable K, lattice K and mineral K) into available form of K [5]. The decrease in available K in treatments receiving only minerals may be due to the dynamic equilibrium maintained between the K forms in soil [12].

### 3.3 Exchangeable K

The data on exchangeable K revealed that the highest mean value of exchangeable K was recorded at 0<sup>th</sup> day in all treatments. After that it was found to be exhibiting a wide variation throughout the incubation period (Fig.1). More amount of exchangeable K content was observed in treatment T<sub>0</sub> (soil alone) at 15<sup>th</sup> day (132.35 kg ha<sup>-1</sup>) and 30<sup>th</sup> day (137.40 kg ha<sup>-1</sup>) followed by treatment T<sub>3</sub> (sylvinite). It was also statistically on par with T<sub>3</sub> at 30<sup>th</sup> day of observation (135.10 kg ha<sup>-1</sup>). From 45 days onwards the highest exchangeable K content was recorded by the treatment T<sub>10</sub> (sylvinite+KSB) which was statistically on par with treatments T<sub>13</sub> (glauconite+KSB), T<sub>3</sub> (sylvinite) and T<sub>7</sub> (rock dust) on 120<sup>th</sup> day's observation.

Exchangeable K is the portion of the soil K that is electrostatically bound as an outer sphere complex to the surfaces of clay minerals and humic substances. It is readily exchanged with other cations and also is readily available to plants [9]. The increase in exchangeable K content may be observed due to more K<sup>+</sup> ions are adsorbed on clay surface. The reaction rate between soil solution and exchangeable phases of K is strongly dependent on the type of clay minerals present [10]. The decrease in K content may be due to release of K from the clay surface to soil solution. The decrease in the K concentration in soil solution triggers the release of K from the exchangeable K fractions [12]. The interaction between the clay content and K concentration in various K minerals showed a significant effect on the exchangeable K content. This may be attributed to the difference in releasing and fixing capacity of different clay minerals present in the soil because the exchangeable K is found with different bond strength at the various sites of clay minerals [4] which was in agreement with the study of transformation of applied K fertilizer in soil.

### 3.4 HNO<sub>3</sub> extractable K

The HNO<sub>3</sub> extractable K content (Table 3) in soil recorded an increase in trend up to 45<sup>th</sup> day of incubation and thereafter

showed a decline in tendency during the incubation period. After 45<sup>th</sup> day there was a decrease in K content was recorded and gradual decrease was observed in all treatment receiving KSB. The treatments receiving K minerals only were showed an increase in K content at last stages of incubation. The highest HNO<sub>3</sub> extractable K content was recorded in treatment T<sub>1</sub> (sulphate of potash) on 180<sup>th</sup> day of incubation (389.55 kg ha<sup>-1</sup>). The lowest value was registered in treatment T<sub>14</sub> (rock dust + KSB) on 180<sup>th</sup> day of incubation (353.80 kg ha<sup>-1</sup>).

The treatments was found insignificant on 0<sup>th</sup> day of incubation which indicates that the addition of K from a mineral or fertilizer source did not have any immediate change in the HNO<sub>3</sub> extractable or fixed K. The initial rise in the HNO<sub>3</sub> extractable K in different treatments may be due to conversion of excess exchangeable K content to the slowly available form. When K is applied in soil, there will be the inter-conversion of different forms of K in order to maintain to maintain the equilibrium level [1]. There was a decrease in K content was observed after 45<sup>th</sup> day with corresponding increase in water soluble and exchangeable fraction of K. Again an increase was observed in treatments receiving minerals alone after 120 days corresponding decrease in water soluble and exchangeable K fractions. This variation may be due to the fixing and releasing of K according to soil environment. The fixation process of K is relatively fast at the beginning and becomes slower when approaches to the equilibrium point, whereas the release of fixed K is very slow due to the strong binding force between K and clay minerals [4, 8].

### 3.5 Non-exchangeable K

Non-exchangeable K content presented in fig 2 was found to be decreased gradually throughout the incubation period and increase in content was observed in the treatment receiving K minerals alone after 150<sup>th</sup> days of incubation. The higher values of non-exchangeable K content were observed on 0<sup>th</sup> day of incubation in all treatments and the highest value recorded in the treatment T<sub>7</sub>

(rock dust, 221.10 kg ha<sup>-1</sup>) followed by the treatment T<sub>5</sub> (kainite) which contains

219.95 kg ha<sup>-1</sup> K.

The reason for the initial decline in K content may be due to the release of K from clay minerals to the soil solution. This indicates that more K<sup>+</sup> ions have tendency to release into soil solution or the fixation process occur in the soil very slowly. The red soil recorded the lowest soil fixing capacity among seven different soils while evaluating the K fixation

capacity in a fifteen year long term fertilization experiment [15]. The non-exchangeable K content in the treatments receiving K minerals along with KSB showed a gradual depletion throughout the incubation period. This may be due to the microbial activity which converts the unavailable form of K to the available form [5].

Fig.2. Non-exchangeable K (kg ha<sup>-1</sup>) released from mineral sources of K with and without KSB

#### 4. CONCLUSION

A wide variation was observed in the amount of K fraction released at different stages of incubation. Regarding the K content in various K pools, there was a gradual

increase and decrease in water soluble, available and exchangeable K content during the incubation period was observed in treatment receiving K minerals alone. But the highest increase in the water soluble, available and exchangeable K was observed in treatments receiving K minerals along with KSB. The non-exchangeable K content was

found to decrease gradually throughout the incubation period and slight increase in content was observed in treatments without KSB. Fluctuation of K pools at different stages is due to the significant relationship of the different forms of K and their relative proportion in soil. The most preferred mineral sources of K like SOP and langbeinite along with KSB can be recommended for increasing the availability of potassium in soil.
