

# Association between phenotypic and genotypic distance matrices of advanced breeding lines of lowland rice (*Oryza sativa* L.) from diverse parents

## Abstract

### Background

The major staple food of the world, rice, is known for preferences in dietary diversification among the communities. Evaluation of advanced breeding lines developed from a set of diverse parents involved in different cross combination facilitates selection of promising genotypes, resource management and planning further breeding activities.

### Method

Totally, 22 advanced breeding lines of lowland rice in F<sub>7</sub> were evaluated based on agromorphologically and genotypically with molecular markers. Here we report correspondence between different distance matrices subjected to correlation based on Mantel test.

### Result

Non significant (p-value > 0.05) correlation was observed between the matrices due to causal factors such as data type, markers used and genetic properties of lines as explained in the text. However, certain promising lines were selected from phenotypic performance as well as molecular fingerprints and grain quality evaluation relative to checks (CAUR1 and Shasarang) with specific context to north eastern hill region.

Keywords: Agro-morphology, rice, distance matrix, molecular markers, Mantel test.

## Introduction

Rice (*Oryza* species) is a monocotyledonous self pollinated plant belonging to the family Poaceae, consumed as a staple food of at least 62 % of planet inhabitants and contributes 29 to 72% caloric intake in different parts of the world (Giraud and Pirzada, 2009). Diversity and variation at species and inter/intra population levels are the inevitable yet explorable elements on which plant breeders primarily depend. They act as tools in designing a breeding program and selection is practiced by identifying diverse lines for many population and line improvement activities such as heterotic grouping (Silva et al. 2020), creation of general combining ability based synthetic populations (Goldringer et al., 2017), donor selections (Allier et al., 2020), narrowing down to best lines as promising varieties and creation of mini cores (Zhang et al., 2012) thus enhancing resource management and breeding activities through evaluation of population structure. Genetic variation is studied from several qualitative and quantitative traits detected from expressed phenotypic variation categorised as morphological technique, in-silico data (Carvalho et al., 2019) and further, from the biochemical and molecular techniques at protein level and DNA sequence level using breeder friendly molecular markers, respectively. Different categorical distance matrices generated from a set of lines under study are compared and related by testing linear independence of its elements by Mantel test (Mantel, 1967) when distance based hypothesis is formulated thus measuring the correlation between the two. The test was first pioneered to compare phenetic distances among local populations to geographic distances (Sokal, 1979). Correspondence level between morphological and molecular dissimilarity distance matrices in crop improvement programs were tested by many workers using Mantel test (Sun et al., 2011; Chung et al., 2011; Zhang et al., 2012; Ehinger et al., 2014; Kaviriri et al., 2020). Chung et al. (2011) reported less inflated type I error rate for Mantel test when comparing with multivariate distance matrix regression.

Advanced breeding lines in self pollinated crops like rice are the genotype material of later generations developed from crossing a set of favourable parental elite lines or landraces. The progeny in each generation undergoes selection for favourable trait expression as per breeding objective and harbour promising better genotype with respect to parents. Such advanced lines are well structured, share ancestry and capable of replacing parental lines in terms of farmer adoption owing to accumulation of favourable alleles after careful within line selections by breeders. However, agronomical and molecular diversity evaluation of these lines is requisite for further utilization as potential genotypes as starting material.

Therefore, the present study was to evaluate the relationship between distance matrices and diversity generated based on phenotypic and genotypic data.

## Materials and Methods

The study was conducted at College of Post Graduate studies, Central Agricultural University (Imphal), Umiam, Meghalaya under rain fed lowland acidic and low available soil phosphorus (P) soil conditions without any management practices during kharif season of 2017-18.

### Breeding materials, experimental design and management:

Twenty two (22) advanced breeding lines of rice in their F<sub>7</sub> generation and 2 standard checks CAUR1 and Shasarang (Table 1). The lines were derived from 8 non aromatic parents consisting of elite varieties and local landraces. The material was sown in randomized block design and traits were measured.

## Data collected

## Phenotypic and genotypic data

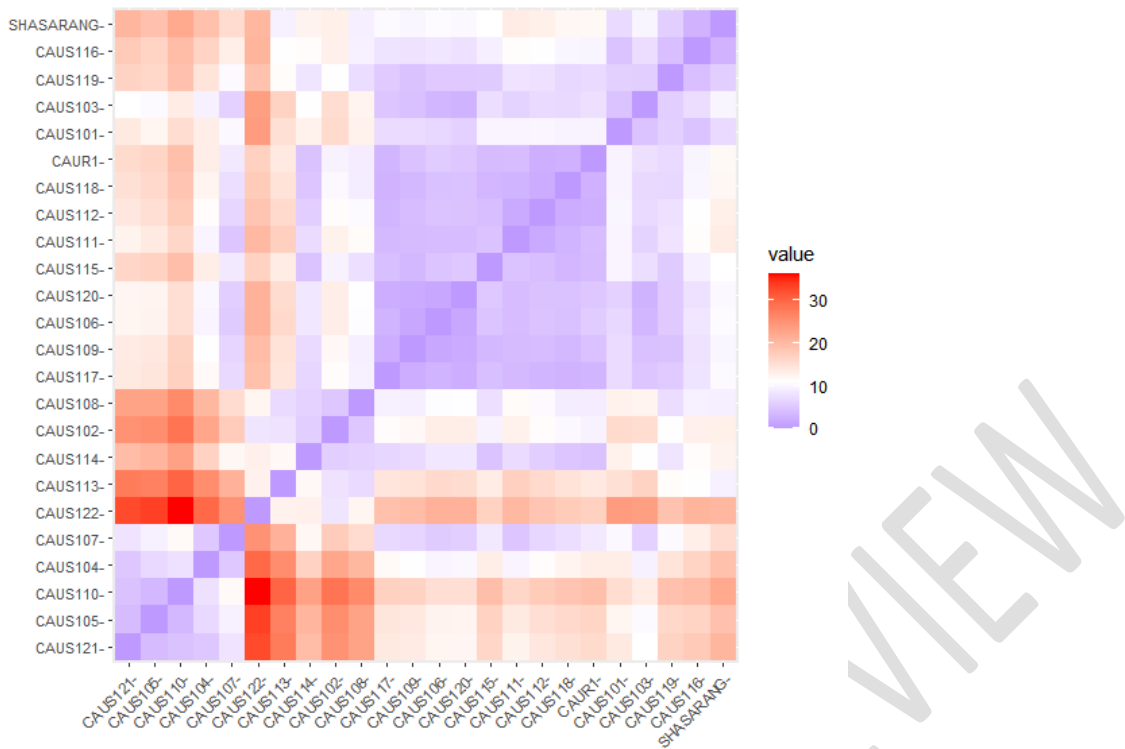

Agro-morphological data was recorded for qualitative and quantitative traits on the lines including DUS traits. Observations on all the morphological characters were recorded on the net plot basis viz., basal leaf sheath color, leaf auricle, leaf ligule, ligule shape, leaf collar, flag leaf: attitude of blade, leaf sheath anthocyanin colouration, leaf blade: anthocyanin, panicle secondary branch, leaf senescence, spikelet: color of tip of lemma, panicle: exertion, panicle: awns, lemma:anthocyanin colouration of area below apex and observations on all the quantitative characters were days to 50 per cent flowering, plant height (cm), tillers per plant, panicle per plant, panicle length (cm), leaf length (cm), leaf width(cm), leaf area index, canopy temperature (0c), biological yield per plant (g), spikelets per plant, number of grains per plant, spikelet fertility (%), harvest index (%), 1000- grain weight, grains yield per plant. Further, the lines were genotyped with a panel of 30 random SSR markers (McCouch *et al.* 2002; <http://www.gramene.org>) and 24 random SNPs.

## Statistical analysis

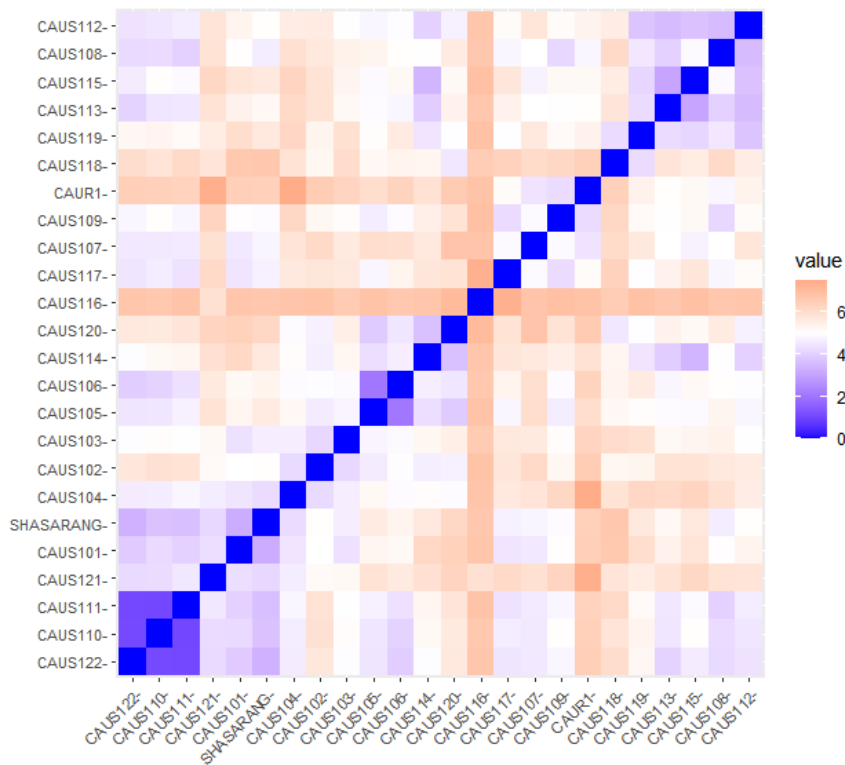

Euclidean distance between lines based on phenotypic and molecular data were measured in R software v4.0.3 using package “stats”. Mantel test for distance matrices was performed with 1000 permutations using “ade4” package of R software v4.0.3 and GenAlEx 6.5 add-in of MS-Excel.

## Results and Discussions

Dissimilarity distance based clustering grouped the advanced breeding lines into two and three major clusters based on phenotypic and genotypic data, respectively based on phenotypic and genotypic distance matrix (Fig. 1 and 2). CAUS116 line was found to be an outlier in the clustering approach based on molecular distance matrix while no outliers were observed in grouping based on phenotypic data (data not shown). Molecular data based clustering grouped certain breeding lines with their either of parents, however, the same pattern was not observed in phenotypic data based clustering as phenotyping for quantitative traits involves environmental effects which could be corrected by multi location evaluation considering genotype-environment interaction. Euclidean distance evaluated based on phenotypic data ranged from 1.44 to 36.17 while the range of 1.03 to 7.34 was observed for genotypic data. The test result used by Mantel is shown in Fig. 2. There was negative and non significant correlation between dissimilarity matrices of genotypic and phenotypic distances with  $r(AB) = -0.177$  ( $p\text{-value} > 0.05$ ). This suggests those molecular and phenotypic categorizations are not identical as observed in clustering dissimilarities. The scatterplot revealed weak  $R^2$  value of 0.03 from regression of matrices.

a) Phenotypic distance matrix

b) Genotypic distance matrix

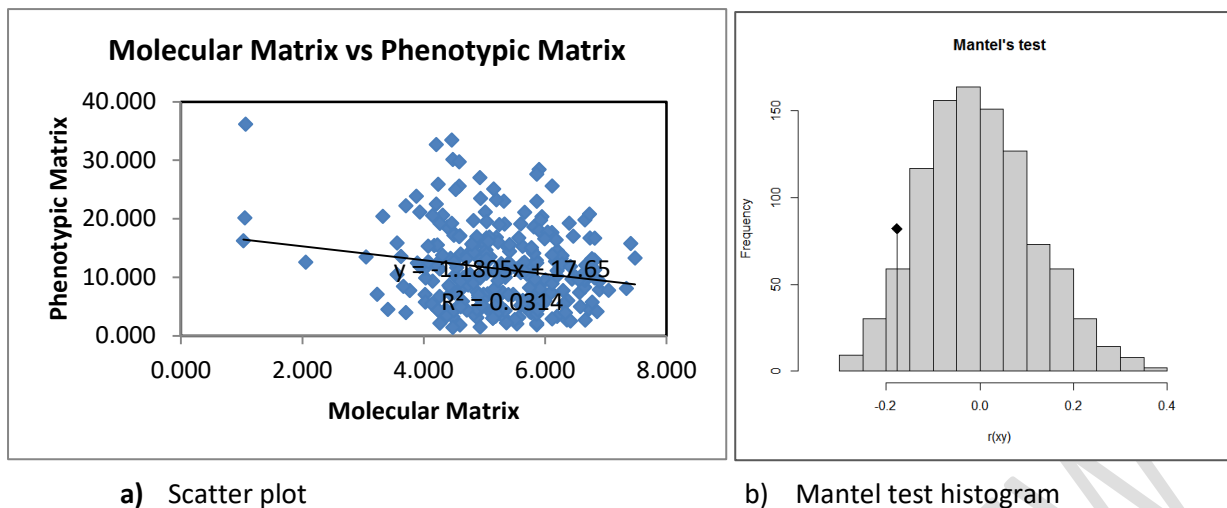

Fig. 2. Representation of correlation analysis between dissimilarity matrices based on phenotypic data and genotypic molecular data. Point corresponds to correlation value.

Several causes contribute to lack of significant correspondence between matrices. Firstly, the nature of data is a major cause. Phenotype is a combination of expression attributed to genotype and environment under the multiple gene control while the molecular data was collected based on random SSRs and SNPs available from non coding regions of DNA. Association of two such distance matrices would be insignificant. Secondly, more number of markers should be included for closely related well structured study material used here to enhance probability of finding linked markers to the quantitative traits which would possibly provide significant Mantel test result or atleast less increase in p-value from 0.05. Thirdly, the advanced breeding lines used here have a locally popular and adapted maternal parent common in most of the cross combinations, causing observation of only 2 major groups in phenotype based clustering approach. Therefore, the genotypes similar to used here are to be evaluated for more phenotypic traits to identify more diversity among the lines. **However, certain promising lines can be identified** with specific reference to molecular fingerprinting, higher phenotypic expression than checks, performance under biotic stress and better grain quality relative to consumer and geographic context.

### Conclusion and recommendation

. The present study was focused on association between agro-morphological and molecular data based dissimilarity distance matrices evaluated on twenty two advanced breeding lines of lowland rice. The study revealed that, non significant differences were observed based on the association between agro-morphological and molecular of the evaluated materials due to the limitation number of molecular markers used at the time of evaluation and other factors. Generally, if the study was conducted with the full methodology, there may be strong correlation among the studied materials in relation to agro-morphological and molecular data and provide basic information for further breeding activities for crop improvement.
